**ABSTRACT.** Explosive volcanic eruptions can inject large quantities of sulphur dioxide into the stratosphere. The aerosols that result from oxidation of the sulphur dioxide can produce significant cooling of the troposphere by reflecting or absorbing solar radiation. It is possible to obtain an estimate of the relative stratospheric sulphur aerosol concentration produced by different volcanoes by comparing sulphuric acid fluxes determined by analysis of polar ice cores. Here, we use a non-sea-salt sulphate time series derived from three well-dated Law Dome ice cores to investigate sulphuric acid flux ratios for major eruptions over the period AD 1301–1995. We use additional data from other cores to investigate systematic spatial variability in the ratios. Only for the Kuwae eruption (Law Dome ice date AD 1459.5) was the  $\text{H}_2\text{SO}_4$  flux larger than that deposited by Tambora (Law Dome ice date AD 1816.7).

## INTRODUCTION

Sulphur-rich gases, principally sulphur dioxide ( $\text{SO}_2$ ) and hydrogen sulphide ( $\text{H}_2\text{S}$ ), emitted by volcanic eruptions have the capability of cooling global climate by a few tenths of a degree for several years following the eruption (Zielinski, 2000, and references therein). For cooling to occur, these gases must be injected into the stratosphere where they are rapidly (within a month of the eruption (Bluth and others, 1993)) oxidized to sulphate ( $\text{SO}_4^{2-}$ ) and sulphuric acid ( $\text{H}_2\text{SO}_4$ ). These aerosols are then rapidly advected around the globe with a time-scale of 2–3 weeks. Meridional transport is much slower, with transport to the polar regions taking about 1–2 years (Robock, 2000, and references therein). The spatial distribution of volcanic aerosols depends upon the location of the eruption, the time of year, the location of the intertropical convergence zone and the quasi-biennial oscillation (Zielinski, 2000). Equatorial eruptions have the greatest potential to influence climate as their aerosols can be transported to both hemispheres. For example, the Mount Pinatubo (Philippines) eruption in June 1991 injected into the atmosphere about  $18 \pm 2 \times 10^9$  kg of  $\text{SO}_2$  (Krueger and others, 1995). This volcanic plume had spread around the Earth by mid-1992, reducing global tropospheric and surface temperatures by 0.2–0.7°C (McCormick and others, 1995; Jones and Kelly, 1996).

Fallout from explosive eruptions like Mount Pinatubo is captured in the polar and tropical ice caps around the globe, as first studied by Hammer (1977). Ice-core volcanic signatures have been used to estimate the optical depth of eruptions prior to instrumental records (Zielinski, 1995, 2000) and the  $\text{H}_2\text{SO}_4$  flux produced by a given eruption (e.g. Moore and others, 1991; Delmas and others, 1992; Clausen and others, 1997; Cole-Dai and others, 1997, 2000). These calculated fluxes can then be compared to the flux of known volcanic signatures such as El Chichón, Mexico (AD 1982), and Mount Pinatubo.

Volcanic signals in ice cores have been detected by electrical conductivity (e.g. Clausen and others, 1997), dielectric profiling (Moore and others, 1991) and trace chemical analysis (e.g. Delmas and others, 1992; Zielinski, 1995; Cole-Dai and others, 2000). The first two methods measure the total acidity of the ice including nitric acid, and other minor acids such as hydrochloric and hydrofluoric acid. The trace chemistry method gives a direct measure of the quantity of  $\text{SO}_4^{2-}$  in the ice.

The  $\text{SO}_4^{2-}$  records presented here were obtained by chemical analysis (Curran and Palmer, 2000) of three ice

Fig. 1. Map of the Antarctic ice cores used in this study, with the Tambora flux values in parentheses (units of  $\text{kg km}^{-2}$ ).

Fig. 2. The residual annual  $\text{H}_2\text{SO}_4$  flux record (AD 1301–1995). Shaded regions highlight periods of volcanic activity in the Law Dome record (Palmer and others, 2001), with starred regions containing multiple eruption signatures.

cores drilled near the summit of Law Dome, a small ice cap abutting the edge of the main East Antarctic ice sheet around  $112^\circ\text{E}$  (Fig. 1). The Law Dome summit region is characterized by high accumulation ( $0.7\text{ m a}^{-1}$  ice equivalent (IE)), relatively low wind speeds ( $8.3\text{ m s}^{-1}$ ) and low mean temperatures ( $-21.8^\circ\text{C}$ ; Morgan and others, 1997). Palmer and others (2001) used multi-parameter annual-layer counting to precisely date the three ice-core records with an age uncertainty of  $\pm 1$  year at AD 1301. Here, we investigate the magnitude of the deposited volcanic  $\text{H}_2\text{SO}_4$  fluxes in the Law Dome ice cores and other previously published Antarctic ice-core records.

## THE VOLCANIC SIGNAL

The main sources of  $\text{SO}_4^{2-}$  in Antarctic ice include sea salt, marine biogenic activity and volcanic fallout. Sea-salt input peaks in late winter with the maximum in storm activity. This noisy signal was removed using the sodium ( $\text{Na}^+$ ) concentration as an indicator of sea-salt input. The non-sea-salt  $\text{SO}_4^{2-}$  ( $\text{nssSO}_4^{2-}$ ) component was calculated using the total  $\text{SO}_4^{2-}$  and  $\text{Na}^+$  concentrations (units  $\mu\text{eq L}^{-1}$ ) and the sea-salt ratio:

$$\text{nssSO}_4^{2-} = [\text{SO}_4^{2-}] - r \times [\text{Na}^+],$$

where  $r = 0.0865$  is the sea-salt ratio of  $\text{SO}_4^{2-}$  to  $\text{Na}^+$  corrected for sea-salt fractionation processes at Law Dome (personal communication from M. Curran, 2001). This correction was calculated using a similar technique to that described by Hall and Wolff (1998).

Marine biogenic activity results in a summer peak in  $\text{SO}_4^{2-}$  at Law Dome. This relatively constant signal was removed from the  $\text{nssSO}_4^{2-}$  record by subtracting a mean seasonal cycle calculated for the entire 695 year record using the technique described by Van Ommen and Morgan (1996). Periods of known volcanic activity identified by Palmer and others (2001) were neglected in the calculation of the mean seasonal cycle.

The amount of volcanic  $\text{H}_2\text{SO}_4$  preserved in the Law

Dome ice-core record for a volcanic signal was estimated from this residual  $\text{nssSO}_4^{2-}$  record by summing the residual  $\text{H}_2\text{SO}_4$  flux for each sample to give a total flux for the duration of the eruption signature. The individual sample fluxes ( $f_s$ , in  $\text{kg km}^{-2} \text{ a}^{-1}$ ) were calculated using

$$f_s = [\text{nssSO}_4^{2-}]_{\text{residual}} \times \frac{\text{MWH}_2\text{SO}_4}{\text{MWSO}_4^{2-}} \times \rho l \times 10^{-3} \quad (\text{kg km}^{-2} \text{ a}^{-1}),$$

where  $[\text{nssSO}_4^{2-}]_{\text{residual}}$  is the residual  $\text{nssSO}_4^{2-}$  concentration in units of  $\mu\text{g kg}^{-1}$ ,  $\text{MWH}_2\text{SO}_4$  and  $\text{MWSO}_4^{2-}$  are the molecular weights of  $\text{H}_2\text{SO}_4$  and  $\text{SO}_4^{2-}$ ,  $\rho = 917\text{ kg m}^{-3}$  (density of ice (Paterson, 1994)), and  $l$  is the depth that would have been covered by a sample (in IE) when it was deposited on the surface (typically  $0.05\text{ m IE}$ ). That is, the sample length has been corrected to account for the apparent reduction in flux due to the spreading of the ice sheet.

The residual annual  $\text{H}_2\text{SO}_4$  flux record for Law Dome is shown in Figure 2. The 20 identified periods of volcanic activity as determined by Palmer and others (2001) are also shown in Figure 2 as shaded regions. Three periods of volcanic activity, denoted by stars in Figure 2, contain multiple eruption signatures that were unable to be clearly resolved with the time-scale graphed in Figure 2.

## SPATIAL VARIABILITY OF VOLCANIC FLUXES

Volcanic  $\text{H}_2\text{SO}_4$  fluxes across the Antarctic continent vary considerably. For example, the Tambora (Indonesia) eruption (Fig. 1), a reference horizon found in most polar ice-core records, has fluxes estimated between  $22.4\text{ kg km}^{-2}$  (Plateau Remote (Cole-Dai and others, 2000)) and  $133\text{ kg km}^{-2}$  (Siple Station (Cole-Dai and others, 1997)). The Tambora flux in the Law Dome ice-core record was  $79.8\text{ kg km}^{-2}$ . Spatial variability studies at South Pole calculated only a 20% variation in  $\text{nssSO}_4^{2-}$  fluxes for the Mount Pinatubo eruption over a calculated  $400\text{ km}^2$  area (Cole-Dai and

Table 1. The volcanic  $H_2SO_4$  flux ratio with respect to the Tambora eruption for seven Antarctic ice cores. The Law Dome ice date for each eruption (Palmer and others, 2001) appears in parentheses. The total Law Dome  $H_2SO_4$  flux for the Tambora eruption was  $79.8 \text{ kg km}^{-2}$

<sup>1</sup> This work.

<sup>2</sup> Siple and Dyer denote the Siple Station and Dyer Plateau ice-core records (Cole-Dai and others, 1997). The unknown volcanic events S9 and D9 (AD 1695–97) and S11 and D11 (AD 1673–75) (Cole-Dai and others, 1997) are attributed to Unknown (AD 1695.8) and Gamkonora, respectively.

<sup>3</sup> GI5 ice-core record was drilled on the Mizuho Plateau (Moore and others, 1991).

<sup>4</sup> The PSI ice-core record is from South Pole (Delmas and others, 1992). The unknown events in AD 1641, 1450 and 1340 are attributed to Parker, Kuwa and Unknown (AD 1345.1), respectively.

<sup>5</sup> The NBY89 ice core is from Byrd Station (Langway and others, 1994). The volcanic events dated AD 1648 and 1605 are attributed to Parker and Huaynaputina, respectively.

<sup>6</sup> PR denotes the Plateau Remote ice core (Cole-Dai and others, 2000). The volcanic event PR 7 (AD 1671) is attributed to Gamkonora. The Krakatau flux ratio was reported by Cole-Dai and others (2000) as a combination of two volcanic events in the PR ice core. Hence this and the Kuwa flux (due to its magnitude) were not included in the mean flux calculations.

Mosley-Thompson, 1999). Studies at Greenland using five ice-core records show similar variability (17%) for the Tambora eruption (Clausen and Hammer, 1988). The variability seen in the South Pole and Greenland studies may be attributed to site characteristics such as surface irregularities (e.g. sastrugi), temperature, wind speed and surface elevation that modulate the local accumulation and hence the flux. It is also possible that some of the variability between the Antarctic ice-core records is a result of the different analytical techniques used to measure the volcanic signal in the ice and calculate the  $H_2SO_4$  flux values (in particular, removal of the non-volcanic background).

The volcanic signals observed in the  $H_2SO_4$  flux records from the various Antarctic sites were compared using the ratio of a volcanic signal to the well-documented volcanic eruption of Tambora (e.g. Moore and others, 1991; Cole-Dai and others, 1997). The use of ratios removes much of the inter-site and analytical variability described above.

Seven Antarctic ice-core records (Fig. 1) were compared for 13 volcanic eruptions where the calculated flux ratios ( $f/f_T$ ) are reported in Table 1. The greatest  $f/f_T$  variability was observed for the Kuwa (Vanuatu) eruption for which the Plateau Remote  $f/f_T$  value appears to be an outlier imposing the need for caution when using this record, as discussed by Cole-Dai and others (2000).

Seven eruptions identified in the Law Dome record (Mount Pinatubo; Cerro Hudson, Chile; El Chichón; Galunggung, Indonesia; Raung, Indonesia; Kelut, Indonesia; and Billy Mitchell, Bougainville) are not included in Table 1, as there were no comparative  $f/f_T$  values in the other records examined. However the Mount Pinatubo and Cerro Hudson  $f/f_T$  may be estimated from two South Pole ice cores (0.16

and 0.04, respectively (Cole-Dai and others, 1999)), where the Law Dome  $f/f_T$  was 0.31 and 0.10, respectively. The trends between these ratios are similar even though the ratios are quite different for the two sites.

The average flux ratio for the volcanic events (excluding Kuwa due to its magnitude) in Table 1 is 0.32 ( $\sigma = 0.14$ ). That is, the magnitude of the low-latitude eruption signatures preserved in the Antarctic ice cap is about one-third that of the Tambora  $H_2SO_4$  flux. Contrasting this, the Kuwa signature had a flux similar to or greater than that of Tambora, depending upon the site, so this eruption might have had an impact on the Earth's climate similar to that of the Tambora eruption, the year following which (AD 1816) was referred to as the “year without a summer”. However, there are few historical records supporting a similar global climatic change following the Kuwa eruption as dated by Palmer and others (2001).

Further evidence for a complex relationship between volcanic aerosols and climate is provided by the Huaynaputina (Peru) eruption in AD 1600. The average  $f/f_T$  for this eruption from seven Antarctic ice cores is 0.30 ( $\sigma = 0.08$ ), about one-third of the  $H_2SO_4$  flux deposited following the Tambora eruption. A temperature time series from a composite of Northern Hemisphere tree-ring records reports the severest short-term cooling event of the past 600 years in AD 1601, the year following the Huaynaputina eruption (Briffa and others, 1998). This suggests that this volcanic eruption had a much larger impact on the Earth's climate than suggested by the Antarctic ice-core  $H_2SO_4$  fluxes. One explanation for this could be that atmospheric circulation patterns favored the dispersal of volcanic aerosols north of the Equator, creating a larger climatic impact in the Northern Hemisphere.

## CONCLUDING REMARKS

Of the 20 volcanic eruptions preserved in the ~700 year Law Dome record, the Tambora and Kuwae signatures had the largest H<sub>2</sub>SO<sub>4</sub> fluxes. Spatial variability studies using 13 volcanic signatures from seven Antarctic sites showed that, on average, low-latitude volcanic eruptions of global importance emit one-third of the H<sub>2</sub>SO<sub>4</sub> produced during the explosive Tambora eruption. However, the H<sub>2</sub>SO<sub>4</sub> volcanic fluxes determined from Antarctic ice cores do not provide a complete picture of the climatic impact of explosive eruptions, and further work comparing various paleoenvironmental records is required to achieve this.

## ACKNOWLEDGEMENTS

A. Palmer acknowledges an Australian Postgraduate Award, and the Trans Antarctic Association for travel assistance. We thank K. Phillips, B. Smith, J. Souney and S. Whitlow for technical assistance.
